

SCIENTIFIC COMMITTEE SECOND REGULAR SESSION

7-18 August 2006
Manila, Philippines
ECOLOGICAL RISK ASSESSMENT FOR SPECIES CAUGHT IN WCPO TUNA FISHERIES: INHERENT RISK AS DETERMINED BY PRODUCTIVITY-SUSCEPTIBILITY ANALYSIS

# Ecological Risk Assessment for species caught in WCPO tuna fisheries: Inherent risk as determined by Productivity-Susceptibility Analysis 

David S. Kirby ${ }^{1}$<br>Oceanic Fisheries Programme, Secretariat of the Pacific Communtity, Noumea.

## 1. INTRODUCTION

Ecological Risk Assessment is a natural resource management system that recognises, among other things, the need for methods of comparative analysis for the numerous species impacted by fisheries. The 1982 UN Convention on the Law of the Sea and the various texts that derive from that, most importantly the WCPO Convention, make little distinction in terms of the management objectives for target and non-target associated and dependent species. All must be maintained at levels above that capable of providing maximum sustainable yield (as qualified by relevant environmental or economic factors); biodiversity must be preserved and ecosystem integrity maintained. There is a general acceptance that highly migratory species (UNCLOS Annex 1) are the primary goup of species that the WCPO Convention and Commission have been designed to manage, yet even these constitute a long list of species, with the authority to add to this list being granted to the Commission under the Convention. Furthermore, there is an obligation to assess the impacts of fishing, other human activities and environmental factors on target stocks, non-target species, and species belonging to the same ecosystem or dependent upon or associated with the target stocks (Article 5). The list of species for which the Commission has responsibility is therefore extremely long and there is a need for the SC to develop a system for comparative analysis of target and non-target associated and dependent species. Such a system would enable prioritisation of fisheries monitoring and research effort, and potential conservation and management measures. Such a system should enable the SC and members of the Commission to meet their obligations under the Convention, as briefly outlined above.

Australia has adapted its exisiting fisheries management systems to incorporate a heirarchical approach to Ecological Risk Assessment. This approach is detailed in EB WP-14. Although it may appear to be very detailed and prescriptive, the general principles are simple, sound and applicable to the WCPO. At its core (Level 2) is a method for comparing the life-history characteristics and fisheries interactions of any number of species, and calculating risk scores for each species based on the most relevant biological criteria: this has been called Productivity-Susceptibility Analysis (PSA). A PSA for WCPO tuna fisheries is presented here in the hope that (a) SC2 will endorse the approach generally, as a basis for prioritisation for fisheries monitoring and research and potential conservation and management measures; (b) that further biological, ecological, and fisheries research into the key variables used in the analysis will be encouraged; (c) there will be iterative improvement in future PSAs presented to the SC; and (d) members of the Commission might carry out similar analyses for tuna fisheries operating within their zones and that they might report the results of such analyses to the SC.

[^0]
### 1.1. WCPFC-2 RESOLUTION ON NON-TARGET FISH SPECIES

In carrying out this exercise, the WCPFC-2 RESOLUTION ON NON-TARGET FISH SPECIES (see below) was kept in mind, as the Ecological Risk Assessment may provide some measure of the degree to which the two parts of the resolution are likely to be effective.

#### Abstract

RESOLUTION ON NON-TARGET FISH SPECIES

The Commission For The Conservation And Management Of Highly Migratory Fish Stocks In The Western And Central Pacific Ocean

In accordance with the Convention on the Conservation and Management of Highly Migratory Fish Stocks in the Western and Central Pacific Ocean:

Noting the importance of many non-target fish species such as mahi mahi, rainbow runner and wahoo for sustainable livelihoods in many communities in the Convention Area;

Recognising the requirement for members of the Commission to adopt measures to minimise discards, catch of non-target fish species, and the impacts on associated or dependent species;

Resolves as follows: 1. Commission Members, Cooperating Non-members and participating Territories (CCMs) shall encourage their vessels operating in fisheries managed under the WCPFC Convention to avoid to the extent practicable, the capture of all non-target fish species that are not retained;

2. Any such non-target fish species that are not to be retained, shall, to the extent practicable, be promptly released to the water unharmed.

The effectiveness of the first part of the resolution (i.e. the degree to which bycatch has been avoided) is illustrated by the catch estimates for non-target species presented in ST IP-1. Whether they are retained and whether their condition is such that they are likely to have been unharmed by their encounter, is recorded by scientific observers and presented here. The effectiveness of the second part of the resolution can therefore also be assessed.

### 1.2. Species List

The list of species included in the analysis comprises all species that have been observed caught by scientific observers and are included in the SPC database covering various observer programmes of the WCPO, including Australia, New Zealand, USA (Hawaii), vessels fishing under the FSM Arrangement and US Multi-Lateral Treaty, and other SPC member country/territory national observer programmes. The list comprises 236 species and 79 species groups, the latter being classifications used by observers when identification to species level was not possible. This list therefore encompasses target species and those associated species ${ }^{2}$ that co-occur in the same fishing area [as the target species] and are exploited (or accidentally taken) in the same fishery or fisheries.

[^1]
## 2. PRODUCTIVITY-SUSCEPTIBILITY ANALYSIS (PSA)

### 2.1. Introduction to Productivity-Susceptibility Analysis (PSA)

When a full stock assessment is carried out it is possible to estimate fishing mortality and its contribution to total mortality for that species. Stock assessments may present biomass depletion ratios comparing $\mathrm{B}_{\text {current }}$ with biomass that would have existed in the absence of fishing. However, data collection for target species is presently far more complete and accurate than that for non-target species and so full stock assessments are not routinely carried out for non-target associated and dependent species. Other methods must therefore be used to assess fishing impacts for these species. The purpose of ProductivitySusceptibility Analysis (PSA) is to provide an objective biological basis for assessing the risk of adverse fisheries impacts upon species caught. Life-history characteristics and measures of fisheries interactions are scored and plotted along two respective axes: productivity and susceptibility.
Productivity ${ }^{3}$ relates to the birth, growth and death rates of a stock. A highly productive stock is characterized by high birth, growth and mortality rates, and as a consequence, a high turn-over and production to biomass ratios (P/B). Such stocks can usually sustain higher exploitation rates and, if depleted, could recover more rapidly than comparatively less productive stocks.

The productivity axis may therefore incorporate life-history characteristics that determine or are reliable indicators of productivity. These include: maximum size; size-at-maturity; maximum age; age-at-maturity; reproductive strategy; fecundity; trophic level.

Susceptibility is the degree to which a species interacts with and is impacted by a fishery. Susceptibility should consider the effects of fisheries encounters, especially those that lead directly or indirectly to mortality, but it may also incorporate the notion of catchability, i.e. behaviour and distribution of the species relative to the distribution and other technical characteristics of the fishery.
PSA attempts to rank a single species relative to the other species in the analysis, along each of the two axes. This may be done for any combination of productivity-susceptibility characteristics considered relevant. However, given that there are multiple factors that may be considered relevant, a composite index for each of the axes may also be derived. The final results may then be ranked by their position on each axis and by a single risk score calculated as the Euclidian distance from the origin of the graph.

If there is confidence in the variables chosen for inclusion and in the quality of the data used for the PSA, it may enable prioritisation of species for more detailed assessments. If data quality is poor or data is lacking it provides a means for focussing monitoring and research efforts in order to obtain that data. It may also inform decisions on management and conservation measures if it constitutes the best scientific information available.

[^2]
### 2.2. Susceptibility

The data used to derive indicators of susceptibility was obtained from the SPC database described above (Section 1.2.). Data queries were performed in order to determine CONDITION AT CAPTURE, LENGTH AT CAPTURE and FATE.

CONDITION AT CAPTURE
There are six categories into which CONDITION AT CAPTURE is classified by observers:
A0: Alive (not further classified)
A1: Alive - injured or distressed
A2: Alive - healthy
A3: Barely alive
D: Dead
U: Unknown condition
The proportion of observations in conditions A3 and D was calculated, with the implicit assumption that the distribution of condition for those recorded as $U$ was represented by the other observations ${ }^{4}$ :

```
CONDITION AT CAPTURE = %Dead = [(A3+D) / (A0+A1+A2+A3+D)]
```

Susceptibility was considered to be proportional to CONDITION AT CAPTURE.
LENGTH AT CAPTURE
The ratios of LENGTH AT CAPTURE / MAXIMUM LENGTH and LENGTH AT CAPTURE / LENGTH AT MATURITY were calculated, with the result being proportional to susceptibility, under the assumption that natural mortality is higher at smaller size (see discussion and cited papers in Working Paper BIO-8 from SCTB17) and that fishing mortality is therefore a smaller component of total mortality than for larger sizes.
FATE
The ratio of DISCARDS / (DISCARDS + RETAINED) was used as an index of FATE. The initial assumption was that DISCARDS are made in the same CONDITION as originally recorded. However, on further consideration this was not deemed appropriate. There are many different subcategories under both DISCARDS and RETAINED and for at least one of these it can be assumed that what has been discarded will not survive: this is for cases where shark fins have been removed and the trunk discarded (Code: DFR). It was therefore necessary to correct the figure for DISCARDS: D* = DISCARDS - (DFR / DISCARDS). Risk under this category was then considered to be inversely proportional to $\mathrm{D}^{*}$. When presenting the productivity-susceptibility plots the corrected PROPORTION RETAINED (i.e. $\mathrm{R}^{*}=100-\mathrm{D}^{*}$ ) is used, in order to maintain the general pattern of the plots: bottom left corner = low risk; top-right corner = high risk.

[^3]Finally, two different composite indices for susceptibility S were calculated.

```
S1 = 1/3 > [(LENGTH AT CAPTURE / MAXIMUM LENGTH) + CONDITION AT CAPTURE +
PROPORTION RETAINED]
S2 = 1/3 > [(LENGTH AT CAPTURE / LENGTH AT MATURITY) + CONDITION AT CAPTURE
+ PROPORTION RETAINED]
```

The results were rescaled to fall between 0 and 1 and the PROPORTION RETAINED includes the proportion of shark discards from which fins were removed as discussed above.

### 2.3. Productivity

Productivity was calculated using data obtained from the literature on maximum size, size-at-maturity; maximum age, age-at-maturity, and reproductive strategy. The size metrics considered were all length-based rather than weight-based. Weight is proportional to volume and therefore tends to increase with length ${ }^{3}$, so length was considered the more sensitive metric. It is also easiest to measure and most often available, allowing published lengths to be compared with those measured by observers.
There are various ways to measure length, e.g. total length, fork length, wing diameter for rays, curved/straight carapace length for turtles. It was not possible to standardise all the length measurements used to populate the databases available. However, when length ratios were calculated, care was taken to ensure that the measures used were comparable.
Length measures are not so appropriate for seabirds and so age data were obtained (Cleo Small pers. comm.). However, comparable age data were not available for many other species and so they were not used in the derivation of composite indices for productivity. This did not preclude the analysis of seabirds in the PSA but they are only considered in the plots of CONDITION AT CAPTURE versus REPRODUCTIVE STRATEGY.

REPRODUCTIVE STRATEGY was considered categorically:
1: Broadcast spawners
2: Egg layers
3: Live bearers
These categories $1-3$ represent decreasing productivity and therefore increasing risk.
Fecundity data (i.e. the number of offpring generated per year) for live-bearing sharks was also obtained from the primary literature (Cortes 2000) in order to illustrate how some sharks are more/less productive than others and thus at less/more risk respectively.

For the final PSA plots (Figures 6 and 7) a composite index for productivity P was calculated as:

P = (REPRODUCTIVE STRATEGY/3) $+($ LENGTH AT MATURITY / MAXIMUM LENGTH)

### 2.4. Number of species for which data were available

The full list of target and non-target associated species comprised 236 species and 79 species groups. Information on life-history and fisheries characteristics determining productivity and susceptibility for these was obtained to the extent listed below:

## Productivity

| Maximum length $\left(\mathrm{L}_{\text {MAX }}\right)$ | 214 species |
| :--- | :--- |
| Maximum age $\left(\mathrm{A}_{\text {MAX }}\right)$ | 82 species |
| Length at maturity $\left(\mathrm{L}_{\mathrm{MAT}}\right)$ | 106 species |
| Age at maturity $\left(\mathrm{A}_{\text {MAT }}\right)$ | 92 species |
| Reproductive strategy | All species and species groups |
| Composite index P | 54 species |

Susceptibility

| Length at capture (L $\mathrm{L}_{\mathrm{CAP}}$ ) | LL | 151 species | 50 species groups |
| :--- | :--- | ---: | :--- |
| L $_{\text {CAP }} / \mathrm{L}_{\text {MAX }}$ | LL | 142 species | - |
| CONDITION | LL | 165 species | 51 species groups |
| FATE | LL | 187 species | 61 species groups |
|  | PS | 73 species | 29 species groups |
| Composite index S1 | LL | 119 species |  |
| Composite index S2 | LL | 75 species |  |

## 3. RESULTS

Figures 1 provides a simple PSA based on only two characteristics: CONDITION AT CAPTURE and MAXIMUM LENGTH. There is no obvious relation between the two variables but none was expected. The results are nonetheless revealing, particularly as it is possible to include a large number of species, but conclusions are better drawn from the plots using the composite indices (Figures 6 and 7).

Figure 2 illustrates the life stage (juvenile/mature) at which the longline fishery impacts the species concerned. From this it is apparent, for example, that the turtles encountered are mostly juvenile, as are many of the sharks, while the target species and other teleosts are largely mature.

Figure 3 illustrates the fact that most seabirds are dead at the time of capture, while most turtles and sharks are not (note that the sample sizes for the highest risk species in this plot - CNX: whitenose shark and RHN: whale shark - are very small). Figure 4 illustrates the fact that birds and turtles are not subsequently retained (note that the sample size for MAH: northern giant petrel, is only 3 individuals for longline and 148 individuals for purse seine). The highest risk group identified in this analysis for longline and in the results for purse seine (Figure 5) are the sharks. While some of these are rarely encountered (e.g. GTF: guitarfishes; 9 observed caught on longline; 0 observed caught on purse seine) others are frequently encountered (e.g. BSH: blue shark; 270423 observed caught on longline. FAL: silky shark; 32591 observed caught on longline and 42497 observed caught by purse seine). Table 2 lists the sharks ranked according to their fecundity; while it would be reasonable to conclude that blue shark is still a relatively low risk as it is one of the most fecund of shark species, silky shark by contrast is one of the least fecund species and therefore at relatively high risk.
The resulting patterns from the two formulations used to develop composite indices for susceptibility (Figures 6 and 7) are quite similar. The species comprising the group with the highest apparent risk (BLR; TRB; CNX; AML; CCP; LMD; HDQ; CCL) is actually rarely encountered, with the exception of AML: grey reef shark, and CCL: blacktip shark, both of which are Annex 1 highly migratory species (see Table 1). There is another group of 16 shark species that also has high apparent risk. Of these, FAL: silky shark, SMA: shortfinned mako, POR: porbeagle, and OCS: oceanic whitetip, are the most observed caught (Table 1) yet they have fecundity less than 15 (Table 2), so they are not especially productive, compared to hammerhead sharks (fecundity > 30) and blue shark (fecundity > 60 ). This puts them at much greater risk than other shark species.
For the teleosts, the most at-risk species are the tunas and billfish plus wahoo and mahi mahi, reflecting the fact that they are target species; their risk scores are therefore due mostly to high susceptibility rather than low productivity. However, stock assessments may still reveal these species to be at risk from overfishing (see SA WP-1 and SA WP-2).

## 4. DISCUSSION AND CONCLUSIONS

No species were excluded a priori from this analysis, even if they are rarely encountered. This is because part of the point of the exercise is to consider the inherent risk to species due to their life-history characteristics in the absence of full information concerning fishing mortality. Even where catch estimates are obtained ( see ST IP-1) there is still no information as to the relative importance of that mortality in the population dynamics of the species concerned. Nonethless, those catch estimates as well as a cursory glance at Table 1 detailing the numbers of individuals observed caught will provide some indication of the confidence one can have in properties calculated from fisheries data and some measure of the extent of fleet-wide fisheries interactions.

The results on CONDITION AT CAPTURE for birds (Figure 3) are unsurprising and demonstrate that effective conservation measures must prevent capture in the first place. For turtles, effective conservation measures can be also directed at treatment post-capture as the survival of these live but probably distressed and fatigued animals may depend on the crew dehooking the turtle without damaging it, and then allowing it to recuperate.
The average proportion landed alive for all shark categories in longline fisheries is $64 \%$. The average whole-body retention rate for all shark categories is $43 \%$ of observed catch. The rest is discarded, but a large proportion of these sharks have had their fins removed: of the total shark discards in the longline fisheries, the average proportion that have had their fins removed and trunk discarded is $50 \%$; for purse seine fisheries this rises to $70 \%$. Thus the average proportion discarded alive is $31 \%$ for longline and $39 \%$ for purse seine. Conservation measures that prohibited the removal of fins from sharks should therefore be effective, assuming the same whole-body retention rate, as the average proportion discarded alive might be expected to rise to the same figure that is landed alive.

Future PSAs should try to derive life-history characteristics for the species groups, where this is appropriate, in order to be able to include more of the observed catch data in the PSAs. However, many species groups are comprised of species that can have quite different life history characteristics (e.g. BIZ, SHK, TUN, TTX) and therefore productivity and susceptibility. The extent to which observed catches are identified to species level has a big influence on the extent to which PSAs may be carried out and the confidence that may be placed in the results. Improving observer coverage and the ability of observers to identify catch to species level is therefore paramount in order to improve the quality of scientific information and advice concerning non-target associated and dependent species. This is particularly true for purse seine fisheries, where LENGTH and CONDITION AT CAPTURE data are also rarely recorded, thus precluding productivitysusceptibility analysis except in terms of PROPORTION RETAINED (PURSE SEINE) versus REPRODUCTIVE STRATEGY (Figure 7).

The extent of vertical and horizontal habitat overlap with fishing effort (e.g. Figure 8) would be an important factor to include in a composite index of susceptibility in future PSAs. Although the information necessary in order to do this with any precision is not likely to exist for all species of interest, it should still be possible to develop an index of spatial vulnerability in both vertical and horizontal dimensions.

There are certainly cases where the available data were poor quality to the point of being misleading. A precautionary approach was always adopted and data that was obviously wrong was not used. However, where the best information available was plausible it was not excluded. In the aftermath of this exercise it is anticipated that a new set of data quality conditions will be added to the observer databases and also that anyone with access to more up-to-date data and information, particularly on life-history characteristics, will make that available to public resource databases such as Fishbase. It is also anticipated that the SC will encourage further research into the fundamental biological characteristics of the more poorly understood target and non-target associated species, based on their risk ranking.

## References and bibliography

For this exercise, data on life-history characteristics were obtained from Cortes (2000) for sharks, Hoelzel (2002) for marine mammals, and from the Fishbase ${ }^{5}$ database for the teleosts. The Status of New Zealand Fisheries website (http://services.fish.govt.nz/indicators/) also proved to be a useful resource. A full list of primary sources is not provided here.

## Figure legends

Figure 1. PSA plot for CONDITION AT CAPTURE versus MAXIMUM LENGTH. This plot is not designed to portray any relationship between the two variables but to highlight those species that have low productivity, denoted in this case by relatively high MAXIMUM LENGTH, and which are unlikely to survive capture, denoted by CONDITION AT CAPTURE. Those species considered to be at relatively low risk are found at the bottom left of the plot and those considered to be at high risk are found at the top right.

Figure 2. LENGTH AT CAPTURE versus MAXIMUM LENGTH. Those species that fall above the $1: 1$ line are mature when captured and therefore considered at relatively higher risk than those that fall below the line, which are caught when juvenile. This conclusion assumes that fishing mortality is a smaller component of total mortality for younger, smaller individuals than for those that are larger and older.

Figure 3. PSA plot for CONDITION AT CAPTURE versus REPRODUCTIVE STRATEGY. Those species considered to be at relatively low risk are found at the bottom left of the plot and those considered to be at high risk are found at the top right.

Figure 4. PSA plot for PROPORTION RETAINED (LONGLINE) versus REPRODUCTIVE STRATEGY. In this case PROPORTION RETAINED has been corrected to include the proportion of discards from which fins had been removed. Those species considered to be at relatively low risk are found at the bottom left of the plot and those considered to be at high risk are found at the top right.

Figure 5. PSA plot for PROPORTION RETAINED (PURSE SEINE) versus REPRODUCTIVE STRATEGY. In this case PROPORTION RETAINED has been corrected to include the proportion of discards from which fins were removed. Those species considered to be at relatively low risk are found at the bottom left of the plot and those considered to be at high risk are found at the top right.

Figure 6. PSA plot using composite indices for productivity and susceptibility. In this case susceptibility S is calculated as: $\mathrm{S}=1 / 3 \times$ [(LENGTH AT CAPTURE / MAXIMUM LENGTH) + CONDITION AT CAPTURE + PROPORTION RETAINED] and productivity P is calculated as $\mathrm{P}=$ (REPRODUCTIVE STRATEGY/3) + LENGTH AT MATURITY / MAXIMUM LENGTH. The results were rescaled to fall between 0 and 1 . The PROPORTION RETAINED has been corrected to include the proportion of discards from which fins were removed.

Figure 7. PSA plot using composite indices for productivity and susceptibility. In this case susceptibility S is calculated as: $\mathrm{S}=1 / 3 \times$ [(LENGTH AT CAPTURE / LENGTH AT MATURITY) + CONDITION AT CAPTURE + PROPORTION RETAINED] and productivity P is calculated as $\mathrm{P}=($ REPRODUCTIVE STRATEGY/3) + LENGTH AT MATURITY / MAXIMUM LENGTH. The results were rescaled to fall between 0 and 1. The Proportion retained has been corrected to include the proportion of discards from which fins were removed.
